# Introduction to R

## **Monta Lokmane**

## **REBCO2**

#### How it works

In the editor on the right you should type R code to solve the exercises. When you hit the 'Submit Answer' button, every line of code is interpreted and executed by R and you get a message whether or not your code was correct. The output of your R code is shown in the console in the lower right corner.

R makes use of the # sign to add comments, so that you and others can understand what the R code is about. Just like Twitter! Comments are not run as R code, so they will not influence your result. For example, Calculate 3 + 4 in the editor on the right is a comment

You can also execute R commands straight in the console. This is a good way to experiment with R code, as your submission is not checked for correctness.

In the editor on the right there is already some sample code. Can you see which lines are actual R code and which are comments? Add a line of code that calculates the sum of 6 and 12, and hit the 'Submit Answer' button.

#### In [ ]:

```
> # Calculate 3 + 4
> 3 + 4
[1] 7
>
> # Calculate 6 + 12
> 6+12
[1] 18
```

### Arithmetic with R

In its most basic form, R can be used as a simple calculator. Consider the following arithmetic operators:

Addition: + Subtraction: - Multiplication: \* Division: / Exponentiation: ^ Modulo: %%

The last two might need some explaining:

The ^ operator raises the number to its left to the power of the number to its right: for example 3^2 is 9. The modulo returns the remainder of the division of the number to the left by the number on its right, for example 5 modulo 3 or 5 %% 3 is 2.

With this knowledge, follow the instructions below to complete the exercise.

Type 2<sup>5</sup> in the editor to calculate 2 to the power 5. Type 28 %% 6 to calculate 28 modulo 6. Click 'Submit Answer' and have a look at the R output in the console. Note how the # symbol is used to add comments on the R code.

```
# An addition
> 5 + 5
[1] 10
> # A subtraction
> 5 - 5
[1] 0
> # A multiplication
> 3 * 5
[1] 15
> # A division
> (5 + 5) / 2
[1] 5
> # Exponentiation
> 2 ^ 5
```

```
[1] 32
> # Modulo
> 28 %% 6
[1] 4
```

## Variable assignment

A basic concept in (statistical) programming is called a variable.

A variable allows you to store a value (e.g. 4) or an object (e.g. a function description) in R. You can then later use this variable's name to easily access the value or the object that is stored within this variable.

You can assign a value 4 to a variable my\_var with the command

```
my_var <- 4
```

Over to you: complete the code in the editor such that it assigns the value 42 to the variable x in the editor. Click 'Submit Answer'. Notice that when you ask R to print x, the value 42 appears.

#### In [ ]:

```
> # Assign the value 42 to x
> x <- 42
> # Print out the value of the variable x
> x
[1] 42
```

## Variable assignment (2)

Suppose you have a fruit basket with five apples. As a data analyst in training, you want to store the number of apples in a variable with the name my\_apples.

Type the following code in the editor: my\_apples <- 5. This will assign the value 5 to my\_apples. Type: my\_apples below the second comment. This will print out the value of my\_apples. Click 'Submit Answer', and look at the console: you see that the number 5 is printed. So R now links the variable my\_apples to the value 5.

#### In [ ]:

```
> # Assign the value 5 to the variable my_apples
> my_apples <- 5
> # Print out the value of the variable my_apples
> my_apples
[1] 5
```

### Variable assignment (3)

Every tasty fruit basket needs oranges, so you decide to add six oranges. As a data analyst, your reflex is to immediately create the variable my\_oranges and assign the value 6 to it. Next, you want to calculate how many pieces of fruit you have in total. Since you have given meaningful names to these values, you can now code this in a clear way:

```
my_apples + my_oranges
```

Assign to my\_oranges the value 6. Add the variables my\_apples and my\_oranges and have R simply print the result. Assign the result of adding my\_apples and my\_oranges to a new variable my\_fruit

```
> # Assign a value to the variables my_apples and my_oranges
> my_apples <- 5
> my_oranges <- 6
> # Add these two variables together
> my_apples + my_oranges
[1] 11
> # Create the variable my_fruit
> my_fruit<- my_apples + my_oranges</pre>
```

## Apples and oranges

Common knowledge tells you not to add apples and oranges. But hey, that is what you just did, no :-)? The my\_apples and my\_oranges variables both contained a number in the previous exercise. The + operator works with numeric variables in R. If you really tried to add "apples" and "oranges", and assigned a text value to the variable my\_oranges (see the editor), you would be trying to assign the addition of a numeric and a character variable to the variable my\_fruit. This is not possible.

Click 'Submit Answer' and read the error message. Make sure to understand why this did not work. Adjust the code so that R knows you have 6 oranges and thus a fruit basket with 11 pieces of fruit.

#### In [ ]:

```
# Assign a value to the variable my_apples
> my_apples <- 5
> # Fix the assignment of my_oranges
> my_oranges <- 6
> # Create the variable my_fruit and print it out
> my_fruit <- my_apples + my_oranges
> my_fruit
[1] 11
```

## Basic data types in R

R works with numerous data types. Some of the most basic types to get started are:

Decimal values like 4.5 are called numerics. Natural numbers like 4 are called integers. Integers are also numerics. Boolean values (TRUE or FALSE) are called logical. Text (or string) values are called characters.

Note how the quotation marks on the right indicate that "some text" is a character.

Change the value of the:

my\_numeric variable to 42. my\_character variable to "universe". Note that the quotation marks indicate that "universe" is a character. my\_logical variable to FALSE

### In [ ]:

```
Change the value of the:

my_numeric variable to 42.

my_character variable to "universe". Note that the quotation marks indicate that "universe" is a character.

my_logical variable to FALSE
```

## What's that data type?

Do you remember that when you added 5 + "six", you got an error due to a mismatch in data types? You can avoid such embarrassing situations by checking the data type of a variable beforehand. You can do this with the class() function, as the code on the right shows.

Complete the code in the editor and also print out the classes of my\_character and my\_logical.

```
> # Declare variables of different types
> my_numeric <- 42
> my_character <- "universe"
> my_logical <- FALSE
> # Check class of my_numeric
> class(my_numeric)
[1] "numeric"
> # Check class of my_character
> class(my_character)
[1] "character"
> # Check class of my_logical
> class(my_logical)
[1] "logical"
```

## Create a vector

Feeling lucky? You better, because this chapter takes you on a trip to the City of Sins, also known as Statisticians Paradise!

Thanks to R and your new data-analytical skills, you will learn how to uplift your performance at the tables and fire off your career as a professional gambler. This chapter will show how you can easily keep track of your betting progress and how you can do some simple analyses on past actions. Next stop, Vegas Baby... VEGAS!!

Do you still remember what you have learned in the first chapter? Assign the value "Go!" to the variable vegas. Remember: R is case sensitive!

#### In [ ]:

```
> # Define the variable vegas
> vegas <- "Go!"
```

# Create a vector (2)

Let us focus first!

On your way from rags to riches, you will make extensive use of vectors. Vectors are one-dimension arrays that can hold numeric data, character data, or logical data. In other words, a vector is a simple tool to store data. For example, you can store your daily gains and losses in the casinos.

In R, you create a vector with the combine function c(). You place the vector elements separated by a comma between the parentheses. For example:

```
numeric_vector <- c(1, 2, 3) character_vector <- c("a", "b", "c")
```

Once you have created these vectors in R, you can use them to do calculations.

Complete the code such that boolean\_vector contains the three elements: TRUE, FALSE and TRUE (in that order).

### In [ ]:

```
> numeric_vector <- c(1, 10, 49)
> character_vector <- c("a", "b", "c")
> # Complete the code for boolean_vector
> boolean_vector <-c(TRUE, FALSE, TRUE)</pre>
```

### Create a vector (3)

After one week in Las Vegas and still zero Ferraris in your garage, you decide that it is time to start using your data analytical superpowers.

Before doing a first analysis, you decide to first collect all the winnings and losses for the last week:

#### For poker\_vector:

```
On Monday you won $140
Tuesday you lost $50
Wednesday you won $20
Thursday you lost $120
Friday you won $240
```

## For roulette\_vector:

```
On Monday you lost $24
Tuesday you lost $50
Wednesday you won $100
Thursday you lost $350
Friday you won $10
```

You only played poker and roulette, since there was a delegation of mediums that occupied the craps tables. To be able to use this data in R, you decide to create the variables poker\_vector and roulette\_vector.

Assign the winnings/losses for roulette to the variable roulette vector

#### In [ ]:

```
> # Poker winnings from Monday to Friday
> poker_vector <- c(140, -50, 20, -120, 240)
> # Roulette winnings from Monday to Friday
> roulette_vector <- c (-24,-50,100,-350,10)</pre>
```

## Naming a vector

As a data analyst, it is important to have a clear view on the data that you are using. Understanding what each element refers to is therefore essential.

In the previous exercise, we created a vector with your winnings over the week. Each vector element refers to a day of the week but it is hard to tell which element belongs to which day. It would be nice if you could show that in the vector itself.

You can give a name to the elements of a vector with the names() function. Have a look at this example:

```
some_vector <- c("John Doe", "poker player") names(some_vector) <- c("Name", "Profession")
```

This code first creates a vector some\_vector and then gives the two elements a name. The first element is assigned the name Name, while the second element is labeled Profession. Printing the contents to the console yields following output:

```
Name Profession
```

"John Doe" "poker player"

The code on the right names the elements in poker\_vector with the days of the week. Add code to do the same thing for roulette vector.

### In [ ]:

```
# Assign days as names of poker_vector
> names(poker_vector) <- c("Monday", "Tuesday", "Wednesday", "Thursday", "Friday")
> # Assign days as names of roulette_vector
> names(roulette_vector)<- c("Monday", "Tuesday", "Wednesday", "Thursday", "Friday")</pre>
```

# Naming a vector (2)

If you want to become a good statistician, you have to become lazy. (If you are already lazy, chances are high you are one of those exceptional, natural-born statistical talents.)

In the previous exercises you probably experienced that it is boring and frustrating to type and retype information such as the days of the week. However, when you look at it from a higher perspective, there is a more efficient way to do this, namely, to assign the days of the week vector to a variable!

Just like you did with your poker and roulette returns, you can also create a variable that contains the days of the week. This way you can use and re-use it.

A variable days\_vector that contains the days of the week has already been created for you. Use days\_vector to set the names of poker\_vector and roulette\_vector.

```
> # Poker winnings from Monday to Friday
> poker_vector <- c(140, -50, 20, -120, 240)
> # Roulette winnings from Monday to Friday
> roulette_vector <- c(-24, -50, 100, -350, 10)
> # The variable days_vector
> days_vector <- c("Monday", "Tuesday", "Wednesday", "Thursday", "Friday")
> # Assign the names of the day to roulette_vector and poker_vector
```

```
> names(poker_vector) <- days_vector
> names(roulette_vector) <-days_vector</pre>
```

# Calculating total winnings

Now that you have the poker and roulette winnings nicely as named vectors, you can start doing some data analytical magic.

You want to find out the following type of information:

```
How much has been your overall profit or loss per day of the week? Have you lost money over the week in total? Are you winning/losing money on poker or on roulette?
```

To get the answers, you have to do arithmetic calculations on vectors.

It is important to know that if you sum two vectors in R, it takes the element-wise sum. For example, the following three statements are completely equivalent:

```
c(1, 2, 3) + c(4, 5, 6) c(1 + 4, 2 + 5, 3 + 6) c(5, 7, 9)
```

You can also do the calculations with variables that represent vectors:

```
a <- c(1, 2, 3) b <- c(4, 5, 6) c <- a + b
```

Take the sum of the variables A\_vector and B\_vector and assign it to total\_vector. Inspect the result by printing out total\_vector.

#### In [ ]:

```
> A_vector <- c(1, 2, 3)
> B_vector <- c(4, 5, 6)
> # Take the sum of A_vector and B_vector
> total_vector <- A_vector+B_vector
> # Print out total_vector
> total_vector
[1] 5 7 9
```

### Calculating total winnings (2)

Now you understand how R does arithmetic with vectors, it is time to get those Ferraris in your garage! First, you need to understand what the overall profit or loss per day of the week was. The total daily profit is the sum of the profit/loss you realized on poker per day, and the profit/loss you realized on roulette per day.

In R, this is just the sum of roulette\_vector and poker\_vector.

Assign to the variable total daily how much you won or lost on each day in total (poker and roulette combined).

### In [ ]:

```
# Poker and roulette winnings from Monday to Friday:
poker_vector <- c(140, -50, 20, -120, 240)
roulette_vector <- c(-24, -50, 100, -350, 10)
days_vector <- c("Monday", "Tuesday", "Wednesday", "Thursday", "Friday")
names(poker_vector) <- days_vector
names(roulette_vector) <- days_vector
# Assign to total_daily how much you won/lost on each day
total_daily <- c(140, -50, 20, -120, 240) + c(-24, -50, 100, -350, 10)</pre>
```

## Calculating total winnings (3)

Based on the previous analysis, it looks like you had a mix of good and bad days. This is not what your ego expected, and you wonder if there may be a very tiny chance you have lost money over the week in total?

A function that helps you to answer this question is sum(). It calculates the sum of all elements of a vector. For example, to calculate the total amount of money you have lost/won with poker you do:

```
total poker <- sum(poker vector)
```

Calculate the total amount of money that you have won/lost with roulette and assign to the variable total\_roulette. Now that you have the totals for roulette and poker, you can easily calculate total\_week (which is the sum of all gains and losses of the week). Print out total week.

#### In [ ]:

```
> # Poker and roulette winnings from Monday to Friday:
> poker_vector <- c(140, -50, 20, -120, 240)
> roulette_vector <- c(-24, -50, 100, -350, 10)
> days_vector <- c("Monday", "Tuesday", "Wednesday", "Thursday", "Friday")
> names (poker_vector) <- days_vector
> names (roulette_vector) <- days_vector
> # Total winnings with poker
> total_poker <- sum(poker_vector)
> # Total winnings with roulette
> total_roulette <- sum(roulette_vector)
> # Total winnings overall
> total_week <- sum(total_roulette+total_poker)
> # Print out total_week
> total_week
```

## **Comparing total winnings**

Oops, it seems like you are losing money. Time to rethink and adapt your strategy! This will require some deeper analysis...

After a short brainstorm in your hotel's jacuzzi, you realize that a possible explanation might be that your skills in roulette are not as well developed as your skills in poker. So maybe your total gains in poker are higher (or > ) than in roulette.

Calculate total\_poker and total\_roulette as in the previous exercise. Use the sum() function twice. Check if your total gains in poker are higher than for roulette by using a comparison. Simply print out the result of this comparison. What do you conclude, should you focus on roulette or on poker?

### In [ ]:

```
> # Poker and roulette winnings from Monday to Friday:
> poker_vector <- c(140, -50, 20, -120, 240)
> roulette_vector <- c(-24, -50, 100, -350, 10)
> days_vector <- c("Monday", "Tuesday", "Wednesday", "Thursday", "Friday")
> names(poker_vector) <- days_vector
> names(roulette_vector) <- days_vector
> # Calculate total gains for poker and roulette
> total_poker <- sum(poker_vector)
> total_roulette <-sum(roulette_vector)
> # Check if you realized higher total gains in poker than in roulette
> total_poker > total_roulette
[1] TRUE
```

## Vector selection: the good times

Your hunch seemed to be right. It appears that the poker game is more your cup of tea than roulette.

Another possible route for investigation is your performance at the beginning of the working week compared to the end of it. You did have a couple of Margarita cocktails at the end of the week...

To answer that question, you only want to focus on a selection of the total\_vector. In other words, our goal is to select specific elements of the vector. To select elements of a vector (and later matrices, data frames, ...), you can use square brackets. Between the square brackets, you indicate what elements to select. For example, to select the first element of the vector, you type poker\_vector[1]. To select the second element of the vector, you type poker\_vector[2], etc. Notice that the first element in a vector has index 1, not 0 as in many other programming languages.

Assign the poker results of Wednesday to the variable poker\_wednesday.

```
In [ ]:
```

```
> # Poker and roulette winnings from Monday to Friday:
```

```
> poker_vector <- c(140, -50, 20, -120, 240)
> roulette_vector <- c(-24, -50, 100, -350, 10)
> days_vector <- c("Monday", "Tuesday", "Wednesday", "Thursday", "Friday")
> names(poker_vector) <- days_vector
> names(roulette_vector) <- days_vector
> # Define a new variable based on a selection
> poker_wednesday <-poker_vector[3]</pre>
```

## Vector selection: the good times (2)

How about analyzing your midweek results?

To select multiple elements from a vector, you can add square brackets at the end of it. You can indicate between the brackets what elements should be selected. For example: suppose you want to select the first and the fifth day of the week: use the vector c(1, 5) between the square brackets. For example, the code below selects the first and fifth element of poker vector:

```
poker vector[c(1, 5)]
```

Assign the poker results of Tuesday, Wednesday and Thursday to the variable poker\_midweek

### In [ ]:

```
> # Poker and roulette winnings from Monday to Friday:
> poker_vector <- c(140, -50, 20, -120, 240)
> roulette_vector <- c(-24, -50, 100, -350, 10)
> days_vector <- c("Monday", "Tuesday", "Wednesday", "Thursday", "Friday")
> names(poker_vector) <- days_vector
> names(roulette_vector) <- days_vector
> # Define a new variable based on a selection
> poker_midweek <- poker_vector[c(2, 3, 4)]</pre>
```

## Vector selection: the good times (3)

Selecting multiple elements of poker\_vector with c(2, 3, 4) is not very convenient. Many statisticians are lazy people by nature, so they created an easier way to do this: c(2, 3, 4) can be abbreviated to 2:4, which generates a vector with all natural numbers from 2 up to 4.

So, another way to find the mid-week results is poker\_vector[2:4]. Notice how the vector 2:4 is placed between the square brackets to select element 2 up to 4.

Assign to roulette\_selection\_vector the roulette results from Tuesday up to Friday; make use of : if it makes things easier for you

#### In [ ]:

```
> # Poker and roulette winnings from Monday to Friday:
> poker_vector <- c(140, -50, 20, -120, 240)
> roulette_vector <- c(-24, -50, 100, -350, 10)
> days_vector <- c("Monday", "Tuesday", "Wednesday", "Thursday", "Friday")
> names(poker_vector) <- days_vector
> names(roulette_vector) <- days_vector
> # Define a new variable based on a selection
> roulette_selection_vector <- roulette_vector[2:5]</pre>
```

### Vector selection: the good times (4)

Another way to tackle the previous exercise is by using the names of the vector elements (Monday, Tuesday, ...) instead of their numeric positions. For example,

```
poker_vector["Monday"]
```

will select the first element of poker\_vector since "Monday" is the name of that first element.

Just like you did in the previous exercise with numerics, you can also use the element names to select multiple elements, for example:

```
poker_vector[c("Monday","Tuesday")]
```

Select the first three elements in poker\_vector by using their names: "Monday", "Tuesday" and "Wednesday". Assign the result of the selection to poker\_start. Calculate the average of the values in poker\_start with the mean() function. Simply print out the result so you can inspect it.

### In [ ]:

```
> # Poker and roulette winnings from Monday to Friday:
> poker_vector <- c(140, -50, 20, -120, 240)
> roulette_vector <- c(-24, -50, 100, -350, 10)
> days_vector <- c("Monday", "Tuesday", "Wednesday", "Thursday", "Friday")
> names(poker_vector) <- days_vector
> names(roulette_vector) <- days_vector

> # Select poker results for Monday, Tuesday and Wednesday
> poker_start <- poker_vector[c("Monday", "Tuesday", "Wednesday")]
> # Calculate the average of the elements in poker_start
> mean(poker_start)
[1] 36.66667
```

## Selection by comparison - Step 1

By making use of comparison operators, we can approach the previous question in a more proactive way.

The (logical) comparison operators known to R are:

```
< for less than
> for greater than
<= for less than or equal to
>= for greater than or equal to
== for equal to each other
!= not equal to each other
```

As seen in the previous chapter, stating 6 > 5 returns TRUE. The nice thing about R is that you can use these comparison operators also on vectors. For example:

```
c(4, 5, 6) > 5 [1] FALSE FALSE TRUE
```

This command tests for every element of the vector if the condition stated by the comparison operator is TRUE or FALSE.

Check which elements in poker\_vector are positive (i.e. > 0) and assign this to selection\_vector. Print out selection\_vector so you can inspect it. The printout tells you whether you won (TRUE) or lost (FALSE) any money for each day.

#### In [ ]:

```
> # Poker and roulette winnings from Monday to Friday:
> poker_vector <- c(140, -50, 20, -120, 240)
> roulette_vector <- c(-24, -50, 100, -350, 10)
> days_vector <- c("Monday", "Tuesday", "Wednesday", "Thursday", "Friday")
> names(poker_vector) <- days_vector
> names(roulette_vector) <- days_vector
> # Which days did you make money on poker?
> selection_vector <- poker_vector > 0
> # Print out selection_vector
> selection_vector
Monday Tuesday Wednesday Thursday Friday
TRUE FALSE TRUE FALSE TRUE
```

## Selection by comparison - Step 2

Working with comparisons will make your data analytical life easier. Instead of selecting a subset of days to investigate yourself (like before), you can simply ask R to return only those days where you realized a positive return for poker.

In the previous exercises you used selection\_vector <- poker\_vector > 0 to find the days on which you had a positive poker return. Now, you would like to know not only the days on which you won, but also how much you won on those days.

You can select the desired elements, by putting selection vector between the square brackets that follow poker vector:

nakar vaatariaalaatian vaatari D kaawa what to da whan you naas a lasiaal vaatar in aswara hraskatar it will anky caleat the alamenta

poker\_vector[selection\_vector] is knows what to do when you pass a logical vector in square prackets: it will only select the elements that correspond to TRUE in selection vector.

Use selection\_vector in square brackets to assign the amounts that you won on the profitable days to the variable poker\_winning\_days.

#### In [ ]:

```
> # Poker and roulette winnings from Monday to Friday:
> poker_vector <- c(140, -50, 20, -120, 240)
> roulette_vector <- c(-24, -50, 100, -350, 10)
> days_vector <- c("Monday", "Tuesday", "Wednesday", "Thursday", "Friday")
> names(poker_vector) <- days_vector
> names(roulette_vector) <- days_vector
> # Which days did you make money on poker?
> selection_vector <- poker_vector > 0
> # Select from poker_vector these days
> poker_winning_days <- poker_vector[selection_vector]</pre>
```

### **Advanced selection**

Just like you did for poker, you also want to know those days where you realized a positive return for roulette.

Create the variable selection\_vector, this time to see if you made profit with roulette for different days. Assign the amounts that you made on the days that you ended positively for roulette to the variable roulette\_winning\_days. This vector thus contains the positive winnings of roulette\_vector.

#### In [ ]:

```
> # Poker and roulette winnings from Monday to Friday:
> poker_vector <- c(140, -50, 20, -120, 240)
> roulette_vector <- c(-24, -50, 100, -350, 10)
> days_vector <- c("Monday", "Tuesday", "Wednesday", "Thursday", "Friday")
> names(poker_vector) <- days_vector
> names(roulette_vector) <- days_vector
> # Which days did you make money on roulette?
> selection_vector <-roulette_vector > 0
> # Select from roulette_vector these days
> roulette_winning_days <- roulette_vector[selection_vector]</pre>
```

### What's a matrix?

In R, a matrix is a collection of elements of the same data type (numeric, character, or logical) arranged into a fixed number of rows and columns. Since you are only working with rows and columns, a matrix is called two-dimensional.

You can construct a matrix in R with the matrix() function. Consider the following example:

```
matrix(1:9, byrow = TRUE, nrow = 3)
```

In the matrix() function:

The first argument is the collection of elements that R will arrange into the rows and columns of the matrix. Here, we use 1:9 which is a shortcut for c(1, 2, 3, 4, 5, 6, 7, 8, 9). The argument byrow indicates that the matrix is filled by the rows. If we want the matrix to be filled by the columns, we just place byrow = FALSE. The third argument nrow indicates that the matrix should have three rows.

Construct a matrix with 3 rows containing the numbers 1 up to 9, filled row-wise.

It is now time to get your hands dirty. In the following exercises you will analyze the box office numbers of the Star Wars franchise. May the force be with you!

In the editor, three vectors are defined. Each one represents the box office numbers from the first three Star Wars movies. The first element of each vector indicates the US box office revenue, the second element refers to the Non-US box office (source: Wikipedia).

In this exercise, you'll combine all these figures into a single vector. Next, you'll build a matrix from this vector.

Use c(new\_hope, empire\_strikes, return\_jedi) to combine the three vectors into one vector. Call this vector box\_office. Construct a matrix with 3 rows, where each row represents a movie. Use the matrix() function to do this. The first argument is the vector box\_office, containing all box office figures. Next, you'll have to specify nrow = 3 and byrow = TRUE. Name the resulting matrix star wars matrix

#### In [ ]:

```
> # Box office Star Wars (in millions!)
> new_hope <- c(460.998, 314.4)
> empire_strikes <- c(290.475, 247.900)
> return_jedi <- c(309.306, 165.8)
> # Create box_office
> box_office <- c(new_hope, empire_strikes, return_jedi)
> # Construct star_wars_matrix
> star_wars_matrix <- matrix(box_office,nrow = 3,byrow = TRUE)</pre>
```

## Naming a matrix

To help you remember what is stored in star\_wars\_matrix, you would like to add the names of the movies for the rows. Not only does this help you to read the data, but it is also useful to select certain elements from the matrix.

Similar to vectors, you can add names for the rows and the columns of a matrix

rownames(my\_matrix) <- row\_names\_vector colnames(my\_matrix) <- col\_names\_vector

We went ahead and prepared two vectors for you: region, and titles. You will need these vectors to name the columns and rows of star wars matrix, respectively.

Use colnames() to name the columns of star\_wars\_matrix with the region vector. Use rownames() to name the rows of star\_wars\_matrix with the titles vector. Print out star\_wars\_matrix to see the result of your work

### In [ ]:

```
> # Box office Star Wars (in millions!)
> new hope <- c(460.998, 314.4)
> empire_strikes <- c(290.475, 247.900)</pre>
> return jedi <- c(309.306, 165.8)</pre>
> # Construct matrix
> star_wars_matrix <- matrix(c(new_hope, empire_strikes, return_jedi), nrow = 3, byrow = TRUE)
> # Vectors region and titles, used for naming
> region <- c("US", "non-US")</pre>
> titles <- c("A New Hope", "The Empire Strikes Back", "Return of the Jedi"
> # Name the columns with region
> colnames(star wars matrix) <- region
> # Name the rows with titles
> rownames(star_wars_matrix)<-titles
> # Print out star_wars_matrix
> star_wars_matrix
                              US non-US
US non-US
A New Hope 460.998 314.4
The Empire Strikes Back 290.475 247.9
Return of the Jedi 309.306 165.8
```

## Calculating the worldwide box office

The single most important thing for a movie in order to become an instant legend in Tinseltown is its worldwide box office figures.

To calculate the total box office revenue for the three Star Wars movies, you have to take the sum of the US revenue column and the non-US revenue column.

In R, the function rowSums() conveniently calculates the totals for each row of a matrix. This function creates a new vector: rowSums(my\_matrix)

Calculate the worldwide box office figures for the three movies and put these in the vector named worldwide\_vector.

### In [ ]:

## Adding a column for the Worldwide box office

In the previous exercise you calculated the vector that contained the worldwide box office receipt for each of the three Star Wars movies. However, this vector is not yet part of star\_wars\_matrix.

You can add a column or multiple columns to a matrix with the cbind() function, which merges matrices and/or vectors together by column. For example:

big\_matrix <- cbind(matrix1, matrix2, vector1 ...)</pre>

Add worldwide vector as a new column to the star wars matrix and assign the result to all wars matrix. Use the cbind() function.

#### In [ ]:

### Adding a row

Just like every action has a reaction, every cbind() has an rbind(). (We admit, we are pretty bad with metaphors.)

Your R workspace, where all variables you defined 'live' (check out what a workspace is), has already been initialized and contains two matrices:

star\_wars\_matrix that we have used all along, with data on the original trilogy, star\_wars\_matrix2, with similar data for the prequels trilogy.

Type the name of these matrices in the console and hit Enter if you want to have a closer look. If you want to check out the contents of the workspace, you can type Is() in the console.

Use rbind() to paste together star\_wars\_matrix and star\_wars\_matrix2, in this order. Assign the resulting matrix to all\_wars\_matrix.

```
> # star_wars_matrix and star_wars_matrix2 are available in your workspace
> star_wars_matrix

US non-US

A New Hope 461.0 314.4
The Empire Strikes Back 290.5 247.9
Return of the Jedi 309.3 165.8
> star_wars_matrix2

US non-US

The Phantom Menace 474.5 552.5
```

```
Attack of the Clones 310.7 338.7
Revenge of the Sith 380.3 468.5
> # Combine both Star Wars trilogies in one matrix
> all_wars_matrix <- rbind(star_wars_matrix,star_wars_matrix2)
```

## The total box office revenue for the entire saga

Just like cbind() has rbind(), colSums() has rowSums(). Your R workspace already contains the all\_wars\_matrix that you constructed in the previous exercise; type all\_wars\_matrix to have another look. Let's now calculate the total box office revenue for the entire saga.

Calculate the total revenue for the US and the non-US region and assign total\_revenue\_vector. You can use the colSums() function. Print out total\_revenue\_vector to have a look at the results.

#### Tn [ ]:

```
> # all wars matrix is available in your workspace
> all_wars_matrix
                           US non-US
A New Hope
                       461.0 314.4
The Empire Strikes Back 290.5 247.9
Return of the Jedi 309.3 165.8
The Phantom Menace 474.5 552.5
Attack of the Clones 310.7 338.7
                       380.3 468.5
Revenge of the Sith
> # Total revenue for US and non-US
> total revenue vector <- colSums(all wars matrix)
> # Print out total revenue vector
> total revenue vector
   US non-US
2226.3 2087.8
```

### Selection of matrix elements

Similar to vectors, you can use the square brackets [] to select one or multiple elements from a matrix. Whereas vectors have one dimension, matrices have two dimensions. You should therefore use a comma to separate the rows you want to select from the columns. For example:

my\_matrix[1,2] selects the element at the first row and second column. my\_matrix[1:3,2:4] results in a matrix with the data on the rows 1, 2, 3 and columns 2, 3, 4.

If you want to select all elements of a row or a column, no number is needed before or after the comma, respectively:

my matrix[,1] selects all elements of the first column. my matrix[1,] selects all elements of the first row.

Back to Star Wars with this newly acquired knowledge! As in the previous exercise, all\_wars\_matrix is already available in your workspace.

Select the non-US revenue for all movies (the entire second column of all\_wars\_matrix), store the result as non\_us\_all. Use mean() on non\_us\_all to calculate the average non-US revenue for all movies. Simply print out the result. This time, select the non-US revenue for the first two movies in all\_wars\_matrix. Store the result as non\_us\_some. Use mean() again to print out the average of the values in non\_us\_some

```
> # Average non-US revenue
> mean(non_us_all)
[1] 347.9667
> # Select the non-US revenue for first two movies
> non_us_some <- all_wars_matrix[1:2,2]
> # Average non-US revenue for first two movies
> mean(non_us_some)
[1] 281.15
```

#### A little arithmetic with matrices

Similar to what you have learned with vectors, the standard operators like +, -, /, \*, etc. work in an element-wise way on matrices in R.

For example, 2 \* my matrix multiplies each element of my matrix by two.

As a newly-hired data analyst for Lucasfilm, it is your job to find out how many visitors went to each movie for each geographical area. You already have the total revenue figures in all\_wars\_matrix. Assume that the price of a ticket was 5 dollars. Simply dividing the box office numbers by this ticket price gives you the number of visitors.

Divide all\_wars\_matrix by 5, giving you the number of visitors in millions. Assign the resulting matrix to visitors. Print out visitors so you can have a look.

#### In [ ]:

```
> # all wars matrix is available in your workspace
> all_wars_matrix
                         US non-US
A New Hope 461.0 314.4
The Empire Strikes Back 290.5 247.9
Return of the Jedi 309.3 165.8
The Phantom Menace
                      474.5 552.5
Attack of the Clones 310.7 338.7
Revenge of the Sith
                      380.3 468.5
> # Estimate the visitors
> visitors <- all wars_matrix/5</pre>
> # Print the estimate to the console
> visitors
                         US non-US
            92.20 62.88
A New Hope
The Empire Strikes Back 58.10 49.58
Return of the Jedi 61.86 33.16
The Phantom Menace
                      94.90 110.50
Attack of the Clones 62.14 67.74
Revenge of the Sith
                      76.06 93.70
```

### A little arithmetic with matrices (2)

Just like 2 my\_matrix multiplied every element of my\_matrix by two, my\_matrix1 my\_matrix2 creates a matrix where each element is the product of the corresponding elements in my\_matrix1 and my\_matrix2.

After looking at the result of the previous exercise, big boss Lucas points out that the ticket prices went up over time. He asks to redo the analysis based on the prices you can find in ticket\_prices\_matrix (source: imagination).

Those who are familiar with matrices should note that this is not the standard matrix multiplication for which you should use %\*% in R.

Divide all\_wars\_matrix by ticket\_prices\_matrix to get the estimated number of US and non-US visitors for the six movies. Assign the result to visitors. From the visitors matrix, select the entire first column, representing the number of visitors in the US. Store this selection as us\_visitors. Calculate the average number of US visitors; print out the result.

```
> ticket prices matrix
              5.0 5.0
A New Hope
The Empire Strikes Back 6.0 6.0
Return of the Jedi 7.0 7.0
The Phantom Menace
                       4.0 4.0
Attack of the Clones 4.5
Revenge of the Sith 4.9
                             4.5
4.9
> # Estimated number of visitors
> visitors <- all wars matrix/ticket prices matrix
> # US visitors
> us visitors <- visitors[,1]</pre>
> # Average number of US visitors
> mean(us visitors)
[1] 75.01401
```

## What's a factor and why would you use it?

In this chapter you dive into the wonderful world of factors.

The term factor refers to a statistical data type used to store categorical variables. The difference between a categorical variable and a continuous variable is that a categorical variable can belong to a limited number of categories. A continuous variable, on the other hand, can correspond to an infinite number of values.

It is important that R knows whether it is dealing with a continuous or a categorical variable, as the statistical models you will develop in the future treat both types differently. (You will see later why this is the case.)

A good example of a categorical variable is sex. In many circumstances you can limit the sex categories to "Male" or "Female". (Sometimes you may need different categories. For example, you may need to consider chromosomal variation, hermaphroditic animals, or different cultural norms, but you will always have a finite number of categories.)

Assign to variable theory the value "factors for categorical variables".

```
In [ ]:
```

```
> # Assign to the variable theory what this chapter is about!
> theory <- "factors for categorical variables"
```

## What's a factor and why would you use it? (2)

To create factors in R, you make use of the function factor(). First thing that you have to do is create a vector that contains all the observations that belong to a limited number of categories. For example, sex\_vector contains the sex of 5 different individuals:

```
sex_vector <- c("Male", "Female", "Female", "Male", "Male"
```

It is clear that there are two categories, or in R-terms 'factor levels', at work here: "Male" and "Female".

The function factor() will encode the vector as a factor:

```
factor_sex_vector <- factor(sex_vector)
```

Convert the character vector sex\_vector to a factor with factor() and assign the result to factor\_sex\_vector Print out factor\_sex\_vector and assert that R prints out the factor levels below the actual values.

```
In [ ]:
```

```
> # Sex vector
> sex_vector <- c("Male", "Female", "Male", "Male")
> # Convert sex_vector to a factor
> factor_sex_vector <-factor(sex_vector)
> # Print out factor_sex_vector
> factor_sex_vector
[1] Male Female Female Male Male
Levels: Female Male
```

### What's a factor and why would you use it? (3)

<del>e</del>n de la companya della companya d

I here are two types of categorical variables: a nominal categorical variable and an ordinal categorical variable.

A nominal variable is a categorical variable without an implied order. This means that it is impossible to say that 'one is worth more than the other'. For example, think of the categorical variable animals\_vector with the categories "Elephant", "Giraffe", "Donkey" and "Horse". Here, it is impossible to say that one stands above or below the other. (Note that some of you might disagree ;-) ).

In contrast, ordinal variables do have a natural ordering. Consider for example the categorical variable temperature\_vector with the categories: "Low", "Medium" and "High". Here it is obvious that "Medium" stands above "Low", and "High" stands above "Medium".

Click 'Submit Answer' to check how R constructs and prints nominal and ordinal variables. Do not worry if you do not understand all the code just yet, we will get to that.

#### In [ ]:

```
> # Animals
> animals_vector <- c("Elephant", "Giraffe", "Donkey", "Horse")
> factor_animals_vector <- factor(animals_vector)
> factor_animals_vector
[1] Elephant Giraffe Donkey Horse
Levels: Donkey Elephant Giraffe Horse
> # Temperature
> temperature_vector <- c("High", "Low", "High", "Low", "Medium")
> factor_temperature_vector <- factor(temperature_vector, order = TRUE, levels = c("Low", "Medium", "High"))
> factor_temperature_vector
[1] High Low High Low Medium
Levels: Low < Medium < High</pre>
```

### **Factor levels**

When you first get a data set, you will often notice that it contains factors with specific factor levels. However, sometimes you will want to change the names of these levels for clarity or other reasons. R allows you to do this with the function levels():

```
levels(factor_vector) <- c("name1", "name2",...)
```

A good illustration is the raw data that is provided to you by a survey. A common question for every questionnaire is the sex of the respondent. Here, for simplicity, just two categories were recorded, "M" and "F". (You usually need more categories for survey data; either way, you use a factor to store the categorical data.)

```
survey_vector <- c("M", "F", "F", "M", "M")
```

Recording the sex with the abbreviations "M" and "F" can be convenient if you are collecting data with pen and paper, but it can introduce confusion when analyzing the data. At that point, you will often want to change the factor levels to "Male" and "Female" instead of "M" and "F" for clarity.

Watch out: the order with which you assign the levels is important. If you type levels(factor\_survey\_vector), you'll see that it outputs [1] "F" "M". If you don't specify the levels of the factor when creating the vector, R will automatically assign them alphabetically. To correctly map "F" to "Female" and "M" to "Male", the levels should be set to c("Female", "Male"), in this order.

Check out the code that builds a factor vector from survey\_vector. You should use factor\_survey\_vector in the next instruction. Change the factor levels of factor\_survey\_vector to c("Female", "Male"). Mind the order of the vector elements here.

### In [ ]:

```
> # Code to build factor_survey_vector
> survey_vector <- c("M", "F", "F", "M", "M")
> factor_survey_vector <- factor(survey_vector)
> # Specify the levels of factor_survey_vector
> levels(factor_survey_vector) <- c("Female", "Male")
> factor_survey_vector
[1] Male Female Female Male Male
Levels: Female Male
```

## Summarizing a factor

After finishing this course, one of your favorite functions in R will be summary(). This will give you a quick overview of the contents of a variable:

```
summary(my var)
```

. .\_ .

Going back to our survey, you would like to know how many "Male" responses you have in your study, and how many "Female" responses. The summary() function gives you the answer to this question.

Ask a summary() of the survey\_vector and factor\_survey\_vector. Interpret the results of both vectors. Are they both equally useful in this case?

#### In [ ]:

```
> # Build factor_survey_vector with clean levels
> survey_vector <- c("M", "F", "F", "M", "M")
> factor_survey_vector <- factor(survey_vector)
> levels(factor_survey_vector) <- c("Female", "Male")
> factor_survey_vector
[1] Male Female Female Male Male
Levels: Female Male

> # Generate summary for survey_vector
> summary(survey_vector)
    Length Class Mode
        5 character character

> # Generate summary for factor_survey_vector
> summary(factor_survey_vector)
Female Male
        2 3
```

### Battle of the sexes

You might wonder what happens when you try to compare elements of a factor. In factor\_survey\_vector you have a factor with two levels: "Male" and "Female". But how does R value these relative to each other?

Read the code in the editor and click 'Submit Answer' to test if male is greater than (>) female.

### In [ ]:

```
> # Build factor_survey_vector with clean levels
> survey_vector <- c("M", "F", "F", "M", "M")
> factor_survey_vector <- factor(survey_vector)
> levels(factor_survey_vector) <- c("Female", "Male")
> # Male
> male <- factor_survey_vector[1]
> # Female
> female <- factor_survey_vector[2]
> # Battle of the sexes: Male 'larger' than female?
> male > female
Warning message: '>' not meaningful for factors
[1] NA
```

### **Ordered factors**

Since "Male" and "Female" are unordered (or nominal) factor levels, R returns a warning message, telling you that the greater than operator is not meaningful. As seen before, R attaches an equal value to the levels for such factors.

But this is not always the case! Sometimes you will also deal with factors that do have a natural ordering between its categories. If this is the case, we have to make sure that we pass this information to R...

Let us say that you are leading a research team of five data analysts and that you want to evaluate their performance. To do this, you track their speed, evaluate each analyst as "slow", "medium" or "fast", and save the results in speed\_vector.

As a first step, assign speed\_vector a vector with 5 entries, one for each analyst. Each entry should be either "slow", "medium", or "fast". Use the list below:

```
Analyst 1 is medium,
Analyst 2 is slow,
Analyst 3 is slow,
Analyst 4 is medium and
Analyst 5 is fast.
```

No need to specify these are factors yet.

```
In [ ]:
```

```
> # Create speed_vector
> speed_vector <- c("medium", "slow", "slow", "medium", "fast")</pre>
```

# Ordered factors (2)

speed\_vector should be converted to an ordinal factor since its categories have a natural ordering. By default, the function factor() transforms speed\_vector into an unordered factor. To create an ordered factor, you have to add two additional arguments: ordered and levels.

```
factor(some vector, ordered = TRUE, levels = c("lev1", "lev2" ...))
```

By setting the argument ordered to TRUE in the function factor(), you indicate that the factor is ordered. With the argument levels you give the values of the factor in the correct order.

From speed\_vector, create an ordered factor vector: factor\_speed\_vector. Set ordered to TRUE, and set levels to c("slow", "medium", "fast").

### In [ ]:

## **Comparing ordered factors**

Having a bad day at work, 'data analyst number two' enters your office and starts complaining that 'data analyst number five' is slowing down the entire project. Since you know that 'data analyst number two' has the reputation of being a smarty-pants, you first decide to check if his statement is true.

The fact that factor\_speed\_vector is now ordered enables us to compare different elements (the data analysts in this case). You can simply do this by using the well-known operators.

Use [2] to select from factor\_speed\_vector the factor value for the second data analyst. Store it as da2. Use [5] to select the factor\_speed\_vector factor value for the fifth data analyst. Store it as da5. Check if da2 is greater than da5; simply print out the result. Remember that you can use the > operator to check whether one element is larger than the other.

### In [ ]:

```
> # Create factor_speed_vector
> speed_vector <- c("medium", "slow", "slow", "medium", "fast")
> factor_speed_vector <- factor(speed_vector, ordered = TRUE, levels = c("slow", "medium", "fast"))
> # Factor value for second data analyst
> da2 <-factor_speed_vector[2]
> # Factor value for fifth data analyst
> da5 <-factor_speed_vector[5]
> # Is data analyst 2 faster than data analyst 5?
> da2 >da5
[1] FALSE
```

## What's a data frame?

You may remember from the chapter about matrices that all the elements that you put in a matrix should be of the same type. Back

then, your data set on Star Wars only contained numeric elements.

When doing a market research survey, however, you often have questions such as:

```
'Are you married?' or 'yes/no' questions (logical)
'How old are you?' (numeric)
'What is your opinion on this product?' or other 'open-ended' questions (character)
...
```

The output, namely the respondents' answers to the questions formulated above, is a data set of different data types. You will often find yourself working with data sets that contain different data types instead of only one.

A data frame has the variables of a data set as columns and the observations as rows. This will be a familiar concept for those coming from different statistical software packages such as SAS or SPSS.

Click 'Submit Answer'. The data from the built-in example data frame mtcars will be printed to the console.

#### In [ ]:

```
> # Print out built-in R data frame
 > mtcars
                                                              mpg cyl disp hp drat

# Quick, have a look at your data set

Wow, that is a lot of cars!

Working with large data sets is not uncommon in data analysis. When you work with (extremely) large data sets and data frames, your first task as a data analyst is to develop a clear understanding of its structure and main elements. Therefore, it is often useful to show only a small part of the entire data set.

So how to do this in R? Well, the function head() enables you to show the first observations of a data frame. Similarly, the function tail() prints out the last observations in your data set.

Both head() and tail() print a top line called the 'header', which contains the names of the different variables in your data set.

Call head() on the mtcars data set to have a look at the header and the first observations.

### In [ ]:

```
> # Call head() on mtcars

> head(mtcars)

mpg cyl disp hp drat wt qsec vs am gear carb

Mazda RX4 21.0 6 160 110 3.90 2.620 16.46 0 1 4 4

Mazda RX4 Wag 21.0 6 160 110 3.90 2.875 17.02 0 1 4 4

Datsun 710 22.8 4 108 93 3.85 2.320 18.61 1 1 4 1

Hornet 4 Drive 21.4 6 258 110 3.08 3.215 19.44 1 0 3 1

Hornet Sportabout 18.7 8 360 175 3.15 3.440 17.02 0 0 3 2

Valiant 18.1 6 225 105 2.76 3.460 20.22 1 0 3 1
```

### Have a look at the structure

Another method that is often used to get a rapid overview of your data is the function str(). The function str() shows you the structure of your data set. For a data frame it tells you:

The total number of observations (e.g. 32 car types) The total number of variables (e.g. 11 car features) A full list of the variables names (e.g. mpg, cyl ... ) The data type of each variable (e.g. num) The first observations

Applying the str() function will often be the first thing that you do when receiving a new data set or data frame. It is a great way to get more insight in your data set before diving into the real analysis.

Investigate the structure of mtcars. Make sure that you see the same numbers, variables and data types as mentioned above.

#### In [ ]:

## Creating a data frame

Since using built-in data sets is not even half the fun of creating your own data sets, the rest of this chapter is based on your personally developed data set. Put your jet pack on because it is time for some space exploration!

As a first goal, you want to construct a data frame that describes the main characteristics of eight planets in our solar system. According to your good friend Buzz, the main features of a planet are:

The type of planet (Terrestrial or Gas Giant). The planet's diameter relative to the diameter of the Earth. The planet's rotation across the sun relative to that of the Earth. If the planet has rings or not (TRUE or FALSE).

After doing some high-quality research on Wikipedia, you feel confident enough to create the necessary vectors: name, type, diameter, rotation and rings; these vectors have already been coded up on the right. The first element in each of these vectors correspond to the first observation.

You construct a data frame with the data.frame() function. As arguments, you pass the vectors from before: they will become the different columns of your data frame. Because every column has the same length, the vectors you pass should also have the same length. But don't forget that it is possible (and likely) that they contain different types of data.

Use the function data.frame() to construct a data frame. Pass the vectors name, type, diameter, rotation and rings as arguments to data.frame(), in this order. Call the resulting data frame planets\_df.

```
> # Definition of vectors
> name <- c("Mercury", "Venus", "Earth", "Mars", "Jupiter", "Saturn", "Uranus", "Neptune")
> type <- c("Terrestrial planet", "Terrestrial planet", "Terrestrial planet",
```

```
"Terrestrial planet", "Gas giant", "Gas giant", "Gas giant", "Gas giant")
> diameter <- c(0.382, 0.949, 1, 0.532, 11.209, 9.449, 4.007, 3.883)
> rotation <- c(58.64, -243.02, 1, 1.03, 0.41, 0.43, -0.72, 0.67)
> rings <- c(FALSE, FALSE, FALSE, TRUE, TRUE, TRUE, TRUE)
> # Create a data frame from the vectors
> planets_df <-data.frame(name, type, diameter, rotation, rings)
```

## Creating a data frame (2)

The planets\_df data frame should have 8 observations and 5 variables. It has been made available in the workspace, so you can directly use it.

Use str() to investigate the structure of the new planets df variable.

## In [ ]:

```
> # Check the structure of planets_df
> str(planets_df)

'data.frame': 8 obs. of 5 variables:

s name : Factor w/ 8 levels "Earth", "Jupiter", ..: 4 8 1 3 2 6 7 5

type : Factor w/ 2 levels "Gas giant", "Terrestrial planet": 2 2 2 2 1 1 1 1

diameter: num 0.382 0.949 1 0.532 11.209 ...

rotation: num 58.64 -243.02 1 1.03 0.41 ...

rings : logi FALSE FALSE FALSE TRUE TRUE ...
```

### Selection of data frame elements

Similar to vectors and matrices, you select elements from a data frame with the help of square brackets []. By using a comma, you can indicate what to select from the rows and the columns respectively. For example:

```
my_df[1,2] selects the value at the first row and second column in my_df. my_df[1:3,2:4] selects rows 1, 2, 3 and columns 2, 3, 4 in my_df.
```

Sometimes you want to select all elements of a row or column. For example, my\_df[1, ] selects all elements of the first row. Let us now apply this technique on planets\_df!

From planets\_df, select the diameter of Mercury: this is the value at the first row and the third column. Simply print out the result. From planets\_df, select all data on Mars (the fourth row). Simply print out the result.

### In [ ]:

```
> # The planets df data frame from the previous exercise is pre-loaded
> planets df
                          type diameter rotation rings
    name
1 Mercury Terrestrial planet 0.382 58.64 FALSE
2 Venus Terrestrial planet 0.949 -243.02 FALSE
3 Earth Terrestrial planet 1.000 1.00 FALSE
                                            1.03 FALSE
                                 0.532
   Mars Terrestrial planet
                                           0.41 TRUE
0.43 TRUE
5 Jupiter Gas giant 11.209
6 Saturn
                    Gas giant
                                  9.449
                  Gas giant 9.449 0.10
Gas giant 4.007 -0.72 TRUE
Gas giant 3.883 0.67 TRUE
7 Uranus
> # Print out diameter of Mercury (row 1, column 3)
> planets df[1,3]
[1] 0.382
> # Print out data for Mars (entire fourth row)
> planets df[4,]
                      type diameter rotation rings
4 Mars Terrestrial planet 0.532 1.03 FALSE
```

### Selection of data frame elements (2)

Instead of using numerics to select elements of a data frame, you can also use the variable names to select columns of a data frame.

Suppose you want to select the first three elements of the type column. One way to do this is

```
planets_df[1:3,2]
```

A possible disadvantage of this approach is that you have to know (or look up) the column number of type, which gets hard if you have a lot of variables. It is often easier to just make use of the variable name:

```
planets_df[1:3,"type"]
```

Select and print out the first 5 values in the "diameter" column of planets\_df.

#### In [ ]:

## Only planets with rings

You will often want to select an entire column, namely one specific variable from a data frame. If you want to select all elements of the variable diameter, for example, both of these will do the trick:

```
planets df[,3] planets df[,"diameter"]
```

However, there is a short-cut. If your columns have names, you can use the \$ sign:

```
planets_df$diameter
```

Use the \$ sign to select the rings variable from planets\_df. Store the vector that results as rings\_vector. Print out rings\_vector to see if you got it right.

### In [ ]:

```
> # planets_df is pre-loaded in your workspace
> # Select the rings variable from planets_df
> rings_vector <- planets_df
$\frac{\$}{\}\rings
> # Print out rings_vector
> rings_vector
[1] FALSE FALSE FALSE TRUE TRUE TRUE
```

## Only planets with rings (2)

You probably remember from high school that some planets in our solar system have rings and others do not. Unfortunately you can not recall their names. Could R help you out?

If you type rings\_vector in the console, you get:

```
[1] FALSE FALSE FALSE TRUE TRUE TRUE TRUE
```

This means that the first four observations (or planets) do not have a ring (FALSE), but the other four do (TRUE). However, you do not get a nice overview of the names of these planets, their diameter, etc. Let's try to use rings\_vector to select the data for the four planets with rings.

The code on the right selects the name column of all planets that have rings. Adapt the code so that instead of only the name column, all columns for planets that have rings are selected.

```
In [ ]:
```

## Only planets with rings but shorter

So what exactly did you learn in the previous exercises? You selected a subset from a data frame (planets\_df) based on whether or not a certain condition was true (rings or no rings), and you managed to pull out all relevant data. Pretty awesome! By now, NASA is probably already flirting with your CV;-).

Now, let us move up one level and use the function subset(). You should see the subset() function as a short-cut to do exactly the same as what you did in the previous exercises.

```
subset(my_df, subset = some_condition)
```

The first argument of subset() specifies the data set for which you want a subset. By adding the second argument, you give R the necessary information and conditions to select the correct subset.

The code below will give the exact same result as you got in the previous exercise, but this time, you didn't need the rings\_vector!

```
subset(planets df, subset = rings)
```

Use subset() on planets\_df to select planets that have a diameter smaller than Earth. Because the diameter variable is a relative measure of the planet's diameter w.r.t that of planet Earth, your condition is diameter < 1

#### In [ ]:

### Sorting

Making and creating rankings is one of mankind's favorite affairs. These rankings can be useful (best universities in the world), entertaining (most influential movie stars) or pointless (best 007 look-a-like).

In data analysis you can sort your data according to a certain variable in the data set. In R, this is done with the help of the function order().

order() is a function that gives you the ranked position of each element when it is applied on a variable, such as a vector for example:

```
a <- c(100, 10, 1000) order(a) [1] 2 1 3
```

10, which is the second element in a, is the smallest element, so 2 comes first in the output of order(a). 100, which is the first element in a is the second smallest element, so 1 comes second in the output of order(a).

This means we can use the output of order(a) to reshuffle a:

```
a[order(a)] [1] 10 100 1000
```

Experiment with the order() function in the console. Click 'Submit Answer' when you are ready to continue.

```
In [ ]:
```

```
> # Play around with the order function in the console
> order()
NULL
```

## Sorting your data frame

Alright, now that you understand the order() function, let us do something useful with it. You would like to rearrange your data frame such that it starts with the smallest planet and ends with the largest one. A sort on the diameter column.

Call order() on planets\_df\$diameter (the diameter column of planets\_df). Store the result as positions. Now reshuffle planets\_df with the positions vector as row indexes inside square brackets. Keep all columns. Simply print out the result

#### In [ ]:

```
> # planets df is pre-loaded in your workspace
> # Use order() to create positions
> positions <- order(planets_df$diameter)</pre>
> # Use positions to sort planets_df
> planets df[positions, ]
                          type diameter rotation rings
    name
1 Mercury Terrestrial planet 0.382 58.64 FALSE 4 Mars Terrestrial planet 0.532 1.03 FALSE
   Mars Terrestrial planet
  Venus Terrestrial planet 0.949 -243.02 FALSE
3 Earth Terrestrial planet 1.000
                                             1.00 FALSE
8 Neptune Gas giant 3.883
                                             0.67 TRUE
                   Gas giant 4.007 -0.72 TRUE
Gas giant 9.449 0.43 TRUE
Gas giant 11.209 0.41 TRUE
7 Uranus
6 Saturn
5 Jupiter
```

## Lists, why would you need them?

Congratulations! At this point in the course you are already familiar with:

```
Vectors (one dimensional array): can hold numeric, character or logical values. The elements in a vector all have the same data type.

Matrices (two dimensional array): can hold numeric, character or logical values. The elements in a matrix all have the same data type.

Data frames (two-dimensional objects): can hold numeric, character or logical values.

Within a column all elements have the same data type, but different columns can be of different data type.
```

Pretty sweet for an R newbie, right? ;-)

Click 'Submit Answer' to start learning everything about lists!

```
In [ ]:
```

```
# Just click the 'Submit Answer' button.
```

## Lists, why would you need them? (2)

A list in R is similar to your to-do list at work or school: the different items on that list most likely differ in length, characteristic, and type of activity that has to be done.

A list in R allows you to gather a variety of objects under one name (that is, the name of the list) in an ordered way. These objects can be matrices, vectors, data frames, even other lists, etc. It is not even required that these objects are related to each other in any way.

You could say that a list is some kind super data type: you can store practically any piece of information in it!

Click 'Submit Answer' to start the first exercise on lists.

```
In [ ]:
```

```
# Click 'Submit Answer' to start the first exercise on lists.
```

## Creating a list

Let us create our first list! To construct a list you use the function list():

```
my list <- list(comp1, comp2 ...)
```

The arguments to the list function are the list components. Remember, these components can be matrices, vectors, other lists, ...

Construct a list, named my list, that contains the variables my vector, my matrix and my df as list components.

#### In [ ]:

```
> # Vector with numerics from 1 up to 10
> my_vector <- 1:10
> # Matrix with numerics from 1 up to 9
> my_matrix <- matrix(1:9, ncol = 3)
> # First 10 elements of the built-in data frame mtcars
> my_df <- mtcars[1:10,]
> # Construct list with these different elements:
> my_list <- list(my_vector,my_matrix,my_df)</pre>
```

# Creating a named list

Well done, you're on a roll!

Just like on your to-do list, you want to avoid not knowing or remembering what the components of your list stand for. That is why you should give names to them:

```
my_list <- list(name1 = your_comp1, name2 = your_comp2)
```

This creates a list with components that are named name1, name2, and so on. If you want to name your lists after you've created them, you can use the names() function as you did with vectors. The following commands are fully equivalent to the assignment above:

```
my_list <- list(your_comp1, your_comp2) names(my_list) <- c("name1", "name2")
```

Change the code of the previous exercise (see editor) by adding names to the components. Use for my\_vector the name vec, for my\_matrix the name mat and for my\_df the name df. Print out my\_list so you can inspect the output.

```
> # Vector with numerics from 1 up to 10
> my vector <- 1:10
> # Matrix with numerics from 1 up to 9
> my matrix <- matrix(1:9, ncol = 3)
> # First 10 elements of the built-in data frame mtcars
> my df <- mtcars[1:10,]</pre>
> # Adapt list() call to give the components names
> my list <- list(vec = my vector, mat = my matrix, df = my df)
> # Print out my list
> my list
$vec
  [1] 1 2 3 4 5 6 7 8 9 10
$mat
       [,1] [,2] [,3]
       1 4 7
[1,]
[2,]
         3
[3,]
                6
$df

## Creating a named list (2)

Being a huge movie fan (remember your job at LucasFilms), you decide to start storing information on good movies with the help of lists.

Start by creating a list for the movie "The Shining". We have already created the variables mov, act and rev in your R workspace. Feel free to check them out in the console.

Complete the code on the right to create shining list; it contains three elements:

moviename: a character string with the movie title (stored in mov) actors: a vector with the main actors' names (stored in act) reviews: a data frame that contains some reviews (stored in rev)

Do not forget to name the list components accordingly (names are moviename, actors and reviews).

#### In [ ]:

```
> # The variables mov, act and rev are available
> # Finish the code to build shining_list
> shining_list <- list(moviename = mov, actors = act, reviews = rev)
```

## Selecting elements from a list

Your list will often be built out of numerous elements and components. Therefore, getting a single element, multiple elements, or a component out of it is not always straightforward.

One way to select a component is using the numbered position of that component. For example, to "grab" the first component of shining\_list you type

```
shining_list[[1]]
```

A quick way to check this out is typing it in the console. Important to remember: to select elements from vectors, you use single square brackets: []. Don't mix them up!

You can also refer to the names of the components, with [[ ]] or with the \$ sign. Both will select the data frame representing the reviews:

shining\_list[["reviews"]] shining\_list\$reviews

Besides selecting components, you often need to select specific elements out of these components. For example, with shining\_list[[2]][1] you select from the second component, actors (shining\_list[[2]]), the first element ([1]). When you type this in the console, you will see the answer is Jack Nicholson.

Select from shining\_list the vector representing the actors. Simply print out this vector. Select from shining\_list the second element in the vector representing the actors. Do a printout like before.

#### In [ ]:

```
> # shining_list is already pre-loaded in the workspace
> # Print out the vector representing the actors
> shining_list sactors
[1] "Jack Nicholson" "Shelley Duvall" "Danny Lloyd" "Scatman Crothers"
[5] "Barry Nelson"
> # Print the second element of the vector representing the actors
> shining_list sactors[2]
[1] "Shelley Duvall"
```

## Adding more movie information to the list

Being proud of your first list, you shared it with the members of your movie hobby club. However, one of the senior members, a guy named M. McDowell, noted that you forgot to add the release year. Given your ambitions to become next year's president of the club, you decide to add this information to the list.

To conveniently add elements to lists you can use the c() function, that you also used to build vectors:

```
ext list <- c(my list, my val)
```

This will simply extend the original list, my\_list, with the component my\_val. This component gets appended to the end of the list. If you want to give the new list item a name, you just add the name as you did before:

```
ext_list <- c(my_list, my_name = my_val)
```

Complete the code below such that an item named year is added to the shining\_list with the value 1980. Assign the result to shining\_list\_full. Finally, have a look at the structure of shining\_list\_full with the str() function.

#### In [ ]:

```
> # shining_list, the list containing movie name, actors and reviews, is pre-loaded in the workspace
> # We forgot something; add the year to shining_list
> shining_list_full <- c(shining_list, year = 1980)
>
> # Have a look at shining_list_full
> str(shining_list_full)
List of 4

| moviename: chr "The Shining"
| actors : chr [1:5] "Jack Nicholson" "Shelley Duvall" "Danny Lloyd" "Scatman Crothers" ...
| reviews : 'data.frame': 3 obs. of 3 variables:
| ... | scores : num [1:3] 4.5 4 5
| ... | scores : Factor w/ 3 levels "IMDb1", "IMDb2", ...: 1 2 3
